(Received 15 December 2007; published 11 September 2008)

All modern routes leading to a quantum theory of gravity—i.e., perturbative quantum gravitational one-loop exact correction to the global chiral current in the standard model, string theory, and loop quantum gravity—require modification of the classical Einstein-Hilbert action for the spacetime metric by the addition of a parity-violating Chern-Simons term. The introduction of such a term leads to spacetimes that manifest an amplitude birefringence in the propagation of gravitational waves. While the degree of birefringence may be intrinsically small, its effects on a gravitational wave accumulate as the wave propagates. Observation of gravitational waves that have propagated over cosmological distances may allow the measurement of even a small birefringence, providing evidence of quantum gravitational effects. The proposed Laser Interferometer Space Antenna (LISA) will be sensitive enough to observe the gravitational waves from sources at cosmological distances great enough that interesting bounds on the Chern-Simons coupling may be found. Here we evaluate the effect of a Chern-Simons induced spacetime birefringence to the propagation of gravitational waves from such systems. Focusing attention on the gravitational waves from coalescing binary black holes systems, which LISA will be capable of observing at redshifts approaching 30, we find that the signature of Chern-Simons gravity is a time-dependent change in the apparent orientation of the binary’s orbital angular momentum with respect to the observer line-of-sight, with the magnitude of change reflecting the integrated history of the Chern-Simons coupling over the worldline of the radiation wave front. While spin-orbit coupling in the binary system will also lead to an evolution of the system’s orbital angular momentum, the time dependence and other details of this real effect are different than the apparent effect produced by Chern-Simons birefringence, allowing the two effects to be separately identified. In this way gravitational-wave observations with LISA may thus provide our first and only opportunity to probe the quantum structure of spacetime over cosmological distances.

I. INTRODUCTION

“Gravitational wave” is the name we give to a short-wavelength feature of the structure of spacetime, the arena within which all other phenomena play out their roles. As such, the direct observation of gravitational waves offers an unprecedented opportunity to explore the environment that both enables and constrains the action of the broader phenomena of nature. Here we describe how, using the proposed Laser Interferometric Gravitational-Wave Antenna (LISA) [1–4], to search for evidence of a correction to general relativity that is well motivated by current experiments to general relativity that is well motivated by current experiments.

In most corners of the perturbative string theory moduli space in 4-dimensionall compactifications, the addition of a parity-violating Chern-Simons term to the Einstein-Hilbert is required for mathematical consistency [5]. Furthermore, in the presence of the Ramond-Ramond scalar (D-instanton charge), the Chern-Simons term is induced in all string theories due to duality symmetries [6,7].

The requirement for a Chern-Simons term is not unique to string-motivated quantum gravity theories: A Chern-Simons correction to the classical Einstein-Hilbert action arises as a perturbative quantum gravitational one-loop exact correction to the global chiral current in the standard model, similar to the anomaly-canceling correction to the QCD path integral [8]. While the anomaly-canceling field in the standard model case interacts with photons (leading to significant observational constraints on its coupling), the anomaly-canceling term considered here affects only the gravitational sector of the theory and is mostly unconstrained by observation [9–11]. A Chern-Simons term also arises in loop quantum gravity, where the coupling is not necessarily limited to small values. In the strong gravity sector of this framework, this term arises to ensure invariance under large gauge transformations of the Ashtekar connection variables [12].

An ad hoc “classical” Chern-Simons “correction” to the classical Einstein-Hilbert action can, of course, always
be introduced, though the prescription for doing so is not unique. In fact, classical realizations of Chern-Simons gravity can generally be made equivalent classical theories of torsion [13,14]. In contrast, when our space-time physics includes both fermions and quantum effects one is led to a specific one-loop exact effective Chern-Simons correction to the Einstein-Hilbert action [14]. Given the ubiquity of a Chern-Simons correction when exploring either perturbative or nonperturbative quantum gravitational effects, and the ad hoc and ambiguous character of its appearance in classical theories, we characterize observational tests for the presence of a Chern-Simons correction to the classical Einstein-Hilbert action as probes of effective quantum gravity.

Chern-Simons corrections to general relativity were first introduced in the context of topologically massive gauge theories in three-dimensional gravity [15]. More recently the three-dimensional theory was generalized to four-dimensional general relativity [16] and, since then, the four-dimensional theory has been studied in cosmological [7,17–19], weak [9–11], and strong gravity contexts [20,21]. In the context of gravitational-wave theory, Chern-Simons gravity leads to an amplitude birefringence of space-time for gravitational-wave propagation [7,16,22]: i.e., a polarization dependent amplification/attenuation of wave amplitude with distance propagated. Observation of gravitational waves that have propagated over cosmological distances, such as will be possible with the Laser Interferometer Gravitational-Wave Observatory (LISA) [2–4], provide the opportunity to measure or bound the magnitude of the birefringence and, correspondingly, provide the first experimental constraints on string theory models of gravity.

Gravitational-wave observations have long been recognized as a tool for testing our understanding of gravity (see [23] for a recent review). Eardley and collaborators [24,25] first proposed a far-field test of all metric theories of gravity through gravitational-wave observations. Finn [26], and later Cutler and Lindblom [27], proposed a means of realizing these measurements using a space-based detector in a circumsolar orbit observing solar oscillations in the far-zone field. Ryan [28] argued that observations of the phase evolution of the gravitational waves emitted during the gravitational-wave driven inspiral of, e.g., a neutron star or stellar mass black hole into a supermassive black hole could be used to “map out” the spacetime metric in the vicinity of the black hole horizon, testing the predictions of general relativity in the regime of strong fields. There have been several proposals describing different ways in which gravitational-wave observations could be used to place bounds on the graviton Compton-wavelength [29–34], the existence of a scalar component to the gravitational interaction [32–35], and the existence of other corrections to general relativity as manifest in some fundamental, dimensionful length scale [36,37].

The measurements we propose here are, we believe, the first example of a direct model-independent probe of string theory and quantum gravity with gravitational waves.

In Sec. II we review Chern-Simons modified gravity, focusing attention on the scale of the Chern-Simons term and its effect on the propagation of gravitational waves in a cosmological background. In Sec. III we evaluate the observational consequences of the Chern-Simons term in the context of ground- and space-based gravitational-wave detectors. In Sec. V we summarize our conclusions and discuss avenues of future research.

Conventions used in relativity work and conventions used in quantum field theory work are often at odds. We follow the relativity conventions Misner, Thorne, and Wheeler [38] in this work: in particular,

(i) Our metric has signature $-+++$;

(ii) We label indices on spacetime tensors with greek characters and use latin indices to label indices on tensors defined on spacelike slices;

(iii) We use a semicolon in an index list to denote a covariant derivative (i.e., $\nabla_{\nu}U$ becomes $V^{\nu}U_{\mu,\nu}$) and a comma to denote ordinary partial derivatives;

(iv) Except where explicitly noted we work in geometric units, wherein $G = c = 1$ for Newtonian gravitational constant $G$ speed of light $c$.

Note that in geometric units, units of mass and length are interchangeable [i.e., $G/c^2$ has units of $(\text{length})/(\text{mass})$]. This is in contrast to Planck units $(\hbar = c = 1)$, where units of mass and units of inverse length are interchangeable (i.e., $\hbar/c$ has units of $(\text{mass}) \times (\text{length})$).

## II. CHERN-SIMONS MODIFIED GRAVITY

### A. Brief review

In this subsection we review the modification to classical general relativity by the inclusion of a Chern-Simons term, based on [16,22]. All four-dimensional compactifications of string theory lead, via the Green-Schwarz anomaly canceling mechanism, to the presence of a four-dimensional gravitational Chern-Simons term [6]. Chern-Simons forms are formally defined for odd dimensions, with the 3-form of particular interest for gauge theories. By introducing an embedding coordinate, which may be dynamical, Jackiw and Yi [16] described a Chern-Simons correction to the Einstein-Hilbert action

$$S_{CS} = \frac{1}{64\pi} \int d^4x \theta R^* R,$$

where $\theta$ is (a functional of) the embedding coordinate

$$R^* R = \frac{1}{2} R_{\alpha\beta\gamma\delta} \epsilon^{\alpha\beta\mu\nu} R_{\mu\nu}^\delta,$$

and $\epsilon^{\alpha\beta\gamma\delta}$ is the Levi-Civita tensor density. The variation with respect to the metric of this contribution to the total action (which includes the Einstein-Hilbert action plus the
action corresponding to any additional matter fields) yields [16]

\[
\delta S_{CS} = -\frac{1}{16\pi} \int d^4x \sqrt{-g} C_{\alpha\beta} \delta g^{\alpha\beta},
\]

where \( g \) is the determinant of the metric and \( C^{\alpha\beta} \) is the C-tensor [39],

\[
C^{\alpha\beta} = -\frac{1}{\sqrt{-g}} \left[ \theta_\beta^{\epsilon\gamma} \partial_\gamma \partial_\delta R^{\delta}_\beta - \partial_\delta \theta_\beta^{\epsilon\gamma} \partial_\gamma R^{\delta}_\beta \right],
\]

and the parenthesis in the superscript stand for symmetrization. The variation of \( S_{CS} \), the usual Einstein-Hilbert action, and the action of other matter fields leads to the equations of motion of Chern-Simons modified gravity

\[
G_{\alpha\beta} + C_{\alpha\beta} = 8\pi T_{\alpha\beta},
\]

where \( G_{\alpha\beta} \) is the Einstein tensor (i.e., the trace-reversed Ricci tensor) and \( T_{\alpha\beta} \) is the stress-energy tensor of the matter fields.

By construction the divergence of the Einstein tensor \( G_{\alpha\beta} \) vanishes. If \( \theta \) is treated as a fixed, external quantity then general covariance, which requires \( \nabla \cdot \mathbf{T} = 0 \), leads to the constraint \( \nabla \cdot C = 0 \), which is shown in [16] to be equivalent to \( R^* R = 0 \). Alternatively, if \( \theta \) is a dynamical field, then variation of the action with respect to \( \theta \) will lead to the same constraint on \( R^* R \). Here we are interested in the propagation of gravitational waves in vacuum, where \( \mathbf{T} = 0 \) and the constraint \( \nabla \cdot C = 0 \) is satisfied regardless of whether we view \( \theta \) as a dynamical field or a fixed, externally-specified quantity.

### B. Linearized Chern-Simons gravitational waves

Focus attention on gravitational-wave perturbations to a Friedmann-Robertson-Walker (FRW) cosmological background in Chern-Simons gravity. Following [22], we can write the perturbed FRW line element as

\[
ds^2 = a^2(\eta) [-d\eta^2 + (\delta_{ij} + h_{ij})d\chi^i d\chi^j],
\]

where \( \eta \) is conformal time, \( \chi^i \) are comoving spatial coordinates, \( \delta_{ij} \) is the Euclidean metric, and \( h_{ij} \) is the metric perturbation, which—for gravitational-wave solutions—we can take to be transverse and traceless [40]. Introducing this perturbation into the field equations [Eq. (2.5)] leads to

\[
\square_{\eta} h_{ij} = -\frac{1}{a^2} \epsilon^{ijkl} [(\theta'') - 2H^2 \theta'] \partial_j h_{ki} + \theta' \partial_p \Box_{\eta} h_{pki},
\]

(2.7)

where we have introduced the notation

\[
' = \partial_{\eta},
\]

(2.8)

\[
\Box_{\eta} = \partial^2_{\eta} - \delta^{ij} \partial_{\eta} \partial_{\eta} + 2H^2 \partial_{\eta},
\]

(2.9)

Conformal time \( \eta \) is related to proper time measured by an observer at rest with respect to the cosmological fluid via

\[
dt = a(\eta)d\eta;
\]

(2.11)

correspondingly, the conformal Hubble function \( H \) is related to the Hubble function \( \dot{H} \) measured by an observer at rest with respect to slices of homogeneity via

\[
H \equiv \frac{\dot{a}}{a} = \frac{1}{a} \dot{H},
\]

(2.12)

where we have use dots to stand for derivatives with respect to cosmic time \( t \).

Focus attention on plane-wave solutions to the wave equation [Eq. (2.7)]. With the ansatz

\[
h_{im}(\eta, \chi^j) = \frac{\mathcal{A}_{im}}{a(\eta)} e^{i(\phi(\eta) - \kappa_n \chi^j)},
\]

(2.13)

where the amplitude \( \mathcal{A}_{im} \), the unit vector in the direction of wave propagation \( n_i \) and the conformal number \( \kappa > 0 \) are all constant, we find that \( \phi, \kappa, \) and \( \mathcal{A}_{ij} \) must satisfy

\[
\mathcal{D} \mathcal{A}_{ij} = -a^{-2} \epsilon^{ijkl} n_p \mathcal{A}_{kl}[(\theta'' - 2H^2 \theta')(\phi' - iH)\kappa + i\theta' \kappa \mathcal{D}],
\]

(2.14)

where

\[
\mathcal{D} = -i\phi'' - (\phi')^2 - \mathcal{H}' - \mathcal{H}^2 + \kappa^2.
\]

(2.15)

Since the Chern-Simons correction breaks parity, it is convenient to resolve \( \mathcal{A}_{ij} \) into definite parity states, corresponding to radiation amplitude in the right- and left-handed polarizations \( e^R_{ij} \) and \( e^L_{ij} \),

\[
\mathcal{A}_{ij} = \mathcal{A}_R e^R_{ij} + \mathcal{A}_L e^L_{ij},
\]

(2.16a)

where

\[
e^R_{kl} = \frac{1}{\sqrt{2}}(e^+_{kl} + ie^-_{kl}),
\]

(2.16b)

\[
e^L_{kl} = \frac{1}{\sqrt{2}}(e^+_{kl} - ie^-_{kl}),
\]

(2.16c)

and \( e^\pm_{kl} \) are the usual linear polarization tensors [38]. It is straightforward to show that

\[
n_i \epsilon^{ijkl} e^R_{kl} = i\lambda_{RL}(e^l)^R_{ij},
\]

(2.17a)

where

\[
\lambda_R = +1,
\]

(2.17b)

\[
\lambda_L = -1.
\]

(2.17c)

With this substitution Eq. (2.14) becomes two decoupled equations, one for right-hand polarized waves and one for
left-hand polarized waves

\[ i \phi''_{RL} + (\phi'_{RL})^2 + \mathcal{H}' + \mathcal{H}^2 - \kappa^2 \]

\[ = \frac{i \lambda_{RL}(\theta'' - 2\mathcal{H}'\theta')(\phi' - i\mathcal{H})\kappa/a^2}{1 - \lambda_{RL}\kappa\theta'/a^2}. \] (2.18)

The terms on the right-hand side of Eq. (2.18) are the Chern-Simons corrections to gravitational plane-wave propagation in a FRW spacetime. To understand the relative scale of these terms, we rewrite the equation in terms of the ratio \( \phi' / \kappa \),

\[ \sum + i(1 - 2\gamma^2) - \delta \Delta - \gamma^2 \]

\[ = \frac{\lambda_{RL}(\epsilon E - 2\gamma \xi \Gamma Z)}{\lambda_{RL}\kappa \epsilon Z} (y - i\gamma \Gamma), \] (2.19a)

where

\[ y = \frac{\phi'}{\kappa}, \] (2.19b)

\[ \gamma = \frac{\mathcal{H}_0}{\kappa} \quad \text{and} \quad \Gamma = \frac{\mathcal{H}}{\mathcal{H}_0}, \] (2.19c)

\[ \delta = \frac{\mathcal{H}_1}{\kappa^2} \quad \text{and} \quad \Delta = \frac{\mathcal{H}'}{\mathcal{H}_0}, \] (2.19d)

\[ \epsilon = \frac{\theta''}{\theta' \kappa'} \quad \text{and} \quad E = \frac{\theta''}{\theta' \kappa'}, \] (2.19e)

\[ \xi = \frac{\kappa \theta_0'}{a_0^2} \quad \text{and} \quad Z = \frac{\kappa \theta'}{a^2 \xi}, \] (2.19f)

and a subscript 0 indicates the present-day value of the functions \( \theta', \theta'', \mathcal{H}, \mathcal{H}', \) and \( a \).

If we assume that \( \theta \) and \( \mathcal{H} \) evolve on cosmological time scales (i.e., \( f' \sim \mathcal{H}(f) \)) then

\[ e^2 \sim (\gamma \xi)^2 \ll \gamma^2 \sim |\delta|. \] (2.20)

Treating the terms in \( \epsilon \) and \( \gamma \xi \) as perturbations, write the solution to Eq. (2.19a) as

\[ y = y_0 + \epsilon y_{0,1} + \gamma \xi y_{1,0} + \ldots, \] (2.21)

where \( y_0 = \phi_0' / \kappa \) is the solution to the unperturbed equation [i.e., the dispersion relation in an FRW cosmology, given by equation (2.19a) with vanishing right-hand side]. The first corrections \( y_{0,1} \) and \( y_{1,0} \) owing to the Chern-Simons terms satisfy

\[ y_{0,1}' - 2i\kappa y_{0,1} = \lambda_{RL}\kappa E y_{0,1}, \] (2.22a)

\[ y_{1,0}' - 2i\kappa y_{1,0} = -2\lambda_{RL}\kappa \Gamma Z y_{0,1}. \] (2.22b)

Requiring that the perturbation vanish at some initial (conformal) time \( \eta_1 \) the perturbations \( y_{0,1} \) and \( y_{1,0} \) satisfy

\[ y_{0,1}(\eta) = \lambda_{RL}[E(\eta), \eta], \] (2.23a)

\[ y_{1,0}(\eta) = -2\lambda_{RL}[\Gamma Z(\eta), \eta]. \] (2.23b)

Finally, the Chern-Simons correction to the accumulated phase as the plane wave propagates from \( \eta_1 \) to \( \eta \) is

\[ \delta \phi_{RL} = \lambda_{RL}\int_{\eta_1}^{\eta} \epsilon y_{[E]}(\eta) - 2\gamma \xi y_{[\Gamma Z]}(\eta). \] (2.24)

When \( \gamma \ll 1 \), i.e., \( k_0 \) is very much greater than the Hubble constant \( H_0 \), the rescaled frequency \( |y_0| \sim 1 \). In this limit we can use integration by parts to find an asymptotic expansion for \( y_g \)

\[ y_g(\eta) \sim \frac{i e^{2i\phi_0(\eta)}}{2} \int_{\eta_1}^{\eta} e^{-2i\phi_0(\eta)} \sum_{n=0}^{\eta} \left( \frac{1}{2iK} \right)^n \left( \frac{1}{y_0 + d\eta} \right)^n \eta \]

\[ + O\left( \frac{1}{2iK} \right)^{n+1}. \] (2.25)

In the next section we explore the observational consequences of gravitational-wave propagation in Chern-Simons gravity.

III. OBSERVATIONAL CONSEQUENCES

A. Birefringence in a matter-dominated cosmology

Current and proposed ground-based gravitational-wave detectors are sensitive to gravitational waves in the 10 Hz–1 KHz band [41–44]. Detectable sources in this band are expected to have redshifts \( z \ll 1 \). Space-based gravitational-wave detectors like LISA [2] will be sensitive to gravitational waves in the 0.1–100 mHz band and, in this band, be sensitive enough to observe the gravitational waves from the inspiral of several \( \sim 10^9 M_\odot \) black hole binary systems at \( z \approx 30 \), i.e., anywhere in the universe they are expected [3,45]. For sources in the band of these detectors

\[ \gamma = 3.7 \times 10^{-19} \left( \frac{h_{100}}{0.72} \right) \left( \frac{1}{kpc/2\pi} \right) \ll 1, \] (3.1)

where

\[ h_{100} = \frac{H_0}{100 \text{ km s}^{-1} \text{ Mpc}^{-1}}. \] (3.2)

Additionally, for redshifts \( z \leq 30 \) the universe is well described by a matter-dominated FRW cosmological model. In this section we evaluate the effect that the Chern-Simons corrections described above have on propagation of gravitational plane waves through a matter-dominated FRW model.
In a matter-dominated FRW model the scale factor $a(t)$ satisfies [38]

$$
\frac{a(\eta)}{a_0} = \eta^2 = \frac{1}{1 + z},
$$

where, by convention, $\eta = 1$ at the present epoch. In this model and with this convention

$$\mathcal{H} = \frac{2}{\eta} = 2\sqrt{1 + z} \quad \text{and} \quad \mathcal{H}_0 = 2,$$

$$\gamma = \frac{2}{\kappa}\quad \text{and} \quad \Gamma = \eta^{-1} = \sqrt{1 + z},$$

$$\delta = -\frac{2}{\kappa^2}\quad \text{and} \quad \Delta = \eta^{-2} = 1 + z,$$

$$\epsilon = \frac{H_0^2}{4} \theta''_0\quad \text{and} \quad E = \frac{1}{\eta^2} \theta''_0,$$

$$
\xi = \frac{H_0 k}{2} \theta'_0 \quad \text{and} \quad Z = \frac{1}{\eta^4} \theta'_0.
$$

Additionally,

$$E = \frac{1}{\eta^4} \theta''_0,$$

$$Z = \frac{1}{\eta^4} \theta'_0,$$

$$a_0 = \frac{\mathcal{H}_0}{H_0} = \frac{2}{H_0}.$$
\[
B(z) = \int_0^t dz (1+z)^{7/2} \frac{d^2 \theta / dz^2}{(d^2 \theta / dz^2)_0},
\]
(3.8e)
\[
\alpha = -\gamma \xi \frac{(d\theta / dz)_0}{2 (d^2 \theta / dz^2)_0 + 3 (d\theta / dz)_0},
\]
(3.8f)
\[
\beta = \frac{\epsilon (d^2 \theta / dz^2)_0}{2 (d^2 \theta / dz^2)_0 + 3 (d\theta / dz)_0},
\]
(3.8g)
and the subscript zero denotes present-day values of the subscripted quantities. The leading-order Chern-Simons correction to the accumulated phase is thus pure imaginary, corresponding to an attenuation of one circular polarization state and an equal amplification of the other. The attenuation/amplification is linearly dependent on the wave number. The function \(\xi(z)\) may be thought of as a “form-factor” that probes the past history of the coupling \(\theta\).

**B. Binary inspiral at cosmological distances**

The proposed LISA gravitational-wave detector is capable of observing coalescing binary black hole systems at cosmological distances; for example, the gravitational waves associated with a pair of \(10^6 M_\odot\) black holes will be observable at redshifts \(z\) approaching 30. Over the year leading up to the merger of two such black holes the binary’s period will decrease by two orders of magnitude, leading to a corresponding decrease in the radiation wavelength and increase in the magnitude of the Chern-Simons correction. The time-dependent relationship between the radiation amplitude in the two polarization states thus carries with it the signature of Chern-Simons gravity and can be used to characterize the functional \(\theta\) that describes the Chern-Simons correction to classical general relativity.

To calculate the signature left by the Chern-Simons correction on the gravitational waves from a coalescing binary system at redshift \(z\), we begin with the radiation near the source. Treating, as before, the Chern-Simons correction as a perturbation, the quadrupole approximation to the radiation from the binary system in the neighborhood of the source is given by

\[
\hat{h} = \Re[\hat{h}_+ e_+ + \hat{h}_\times e_\times],
\]
(3.9a)
\[
\hat{h}_+ = \frac{2 \hat{M}}{d} \left[1 + \hat{\chi}^2 \right] \hat{M} \hat{k} / 2 \left[2/3 \right] \exp[-i(\hat{\Phi}(\hat{t}) - \hat{k}(\hat{t}) d)],
\]
(3.9b)
\[
\hat{h}_\times = \frac{4 i \hat{M}}{d} \hat{\chi} \left[\hat{M} \hat{k} / 2 \left[2/3 \right] \exp[-i(\hat{\Phi}(\hat{t}) - \hat{k}(\hat{t}) d)],
\]
(3.9c)

where \(d\) is the proper distance to the source and

\[
\hat{\Phi}(\hat{t}) = -2 \left(\frac{\hat{T} - \hat{\eta}^5}{5 \hat{M}}\right) + \hat{\delta},
\]
(3.10)
\[
\hat{k}(\hat{t}) = \frac{2}{\hat{M}} \left(\frac{5}{256} \left[\frac{\hat{M}}{T - \hat{t}}\right]\right)^{3/8}.
\]
(3.11)

The constants \(\hat{T}\) and \(\hat{\delta}\), which determine when coalescence occurs and the phase of the gravitational-wave signal at some fiducial instant, are set by initial conditions. The quantities \(\hat{M}\) and \(\hat{\chi}\) are constants that depend on the binary system’s component masses \((m_1, m_2)\) and orientation with respect to the observer

\[
\hat{\chi} = \text{(cosine-angle between the orbital angular momentum and the observer line-of-sight)},
\]
(3.12a)
\[
\hat{M} = \frac{m_1^{3/5} m_2^{3/5}}{(m_1 + m_2)^{1/5}} = \text{("chirp" mass)},
\]
(3.12b)

We “hat” all these quantities to remind us that, as expressed above, they are appropriate descriptions only in the neighborhood of the source where the Chern-Simons and cosmological corrections to the propagation of the waves may be neglected.

To describe the radiation after it has propagated to the detector we first describe the near-source radiation in terms of circular polarization states

\[
\hat{h} = \Re[\hat{h}_R e_R + \hat{h}_L e_L],
\]
(3.13a)
\[
\hat{h}_{RL} = \sqrt{2} \hat{M} \hat{k}_0 \left(\frac{2}{\hat{M}}\right)^{2/3} \left(1 + \lambda_{RL} \hat{\chi}\right)^2 \times \exp[-i(\hat{\Phi}(\hat{t}) - \hat{k}(\hat{t}) d)],
\]
(3.13b)

We are interested in the radiation incident on our detector today \((z = 0, \eta = 1)\) from a source at redshift \(z\). Matching the near-source description of the radiation [Eq. (3.13)] to our ansatz [Eq. (2.13)] we find the description of the radiation after propagating to the detector from a redshift \(z\),

\[
\hat{h} = \Re[\hat{h}_R e_R + \hat{h}_L e_L],
\]
(3.14a)
\[
\hat{h}_{RL} = \sqrt{2} \frac{\hat{M} \hat{k}_0}{d_L} \left(\frac{2}{\hat{M}}\right)^{2/3} (1 + \lambda_{RL} \hat{\chi})^2 \times \exp[-i(\hat{\Phi}_0(t) - \kappa(1 - \eta) + \Delta \phi_0(t) + \Delta \phi_{1(RL)}(t))],
\]
(3.14b)

where

\[
\Phi_0(t) = -2 \left(\frac{T - \eta^5}{5 \hat{M}}\right) + \hat{\delta},
\]
(3.14c)
\[
k_0(t) = \frac{2}{\hat{M}} \left(\frac{5}{256} \left[\frac{\hat{M}}{T - \hat{t}}\right]\right)^{3/8}.
\]
(3.14d)
The correction through the time-dependent cosmological background.

The correction \( \Delta \phi_0 \), which is the same for all polarizations, embodies the time-dependent cosmological background. The correction \( \Delta \phi_{1(\text{RL})} \) is of opposite character for the two polarization states and embodies the (first-order) corrections to wave propagation owing to the Chern-Simons corrections to the Einstein field equations.

Focus attention on the argument of the exponential in Eq. (3.14b). The term \( \kappa(1-\eta) \) cancels the first term in Eq. (3.14g) for \( \Delta \phi_0 \), leading to

\[
h_{R,L} = \sqrt{2} \frac{\mathcal{M}}{d_L} \left( \frac{\mathcal{M} k_0}{2} \right)^{2/3} (1 + \lambda_{R,L} \hat{x})^2 \times \exp \left[ -i(\Phi_0(t) - \frac{\gamma(t)}{2} (\sqrt{1+z} - 1) + \Delta \phi_{1(\text{RL})}(t)) \right]. \tag{3.15} \]

The observational effect of the Chern-Simons is readily identified by looking at the ratio of the polarization amplitudes \( h_R \) and \( h_L \),

\[
\frac{h_R}{h_L} = \frac{(1 + \hat{x})}{(1 - \hat{x})} \exp \left[ \frac{2k(t)\xi(z)}{H_0} \right]. \tag{3.16} \]

where \( \xi \) is given by Eq. (3.8) and \( x \) may be interpreted as the apparent inclination cosine-angle. The effect of the Chern-Simons correction on gravitational-wave propagation is to confound the identification between polarization amplitude ratios and binary orbit inclination cosine-angle. In the same way that we say that the curvature of spacetime "bends" light passing close to strongly gravitating body we may say that the effect of the Chern-Simons correction is to “rotate” the apparent inclination angle of the binary system’s orbital angular momentum axis either toward or away from us.

IV. DISCUSSION

A. What can be measured?

Over the course of a year-long observation the LISA spacecraft constellation will measure the radiation in both polarizations of an incident gravitational-wave train associated with an inspiraling coalescing binary system. The relative amplitude of the two polarizations will be determined by the orientation of the binary systems orbital plane to the observer line-of-sight and the form factor \( \xi(z) \). A nonvanishing \( \xi \) leads to a time-varying apparent inclination angle that, by nature of its time dependence, can (in principle) be measured directly from the apparent inclination angle’s time variation.

Other properties of an inspiraling binary can lead to an evolution of the (apparent) inclination cos-angle. Spin-orbit coupling leads to a real precession of the binary’s orbital plane and a corresponding time-dependence in the actual inclination cos-angle \( \hat{x} \). Referring to Eq. (3.14b), it is apparent that for small \( |\hat{x}| \sim 0 \) an incremental change \( \mu \) in \( \hat{x} \) will lead to changes in \( h_{R,L} \) that are indistinguishable from an increment in \( x \) associated with \( \xi \). Following Vecchio ([46] Eqs. 27–31) we note that, at first nonvanishing post-Newtonian order, spin-orbit interactions in an inspiraling binary system lead to

\[
\left( \frac{d\hat{x}}{dt} \right) \approx k_0^{2/3}(t). \tag{4.1} \]

This is a different dependence on \( k_0 \) than the \( O(k_0) \) dependence associated with \( \xi \). Thus, it remains in principle possible to distinguish the signature of Chern-Simons gravity in the signal from cosmologically distant coalescing binary black hole systems. The accuracy with which such a measurement can be made is the topic of the next subsection.

B. How accurately can \( \xi \) be measured?

The most general astrophysical black hole binary system can be described by eleven independent parameters, which may be counted as two component masses; component spins and their orientation (six parameters); orbital eccentricity; orbital phase; and a a reference time when the phase, spins and eccentricity are measured. The gravitational-wave signal in any particular polarization will depend on the description of the binary and six additional parameters that describe the binary’s orientation with respect to the detector. These six additional parameters may be counted as orbital plane orientation (two angles); source location with respect to the detector (distance and two position angles); and orbit orientation in orbital plane (one angle) [47]. To these seventeen parameters we now add \( \xi \), which describes the effect of propaga-
tion through the birefringent Chern-Simons spacetime, for a total of eighteen parameters that are required to describe the signal from a coalescing binary system.

To-date, all analyses of expected parameter estimation errors have been made under a set of approximations that focus attention on the measurement of component masses, source location (both distance and angular position), and the expected time of binary coalescence. Even the most sophisticated of these analysis ignore all but the leading-order contribution to the gravitational-wave signal amplitude at twice the orbital frequency [48] and assume that the orbital eccentricity is known to vanish. These approximations are quite appropriate for their purpose (estimation of component masses, source location, and expected time of coalescence); however, by ignoring all but the leading-order contribution to the signal magnitude they are inadequate starting points for exploring the accuracy with which \( \xi \), which affects only the signal amplitude in the different polarizations, can be bounded [49]. Evaluating and presenting the errors associated with the measurement of \( \xi \) via a full covariance matrix analysis is thus a formidable enterprise, to be addressed in a future work.

Nevertheless, through a series of plausible approximations it is possible to make a crude estimate of the accuracy with which \( \xi \) can be determined. To begin, assume we have two gravitational-wave detectors such that, via a linear combination of observations made at each, we can synthesize two other detectors with one exclusively sensitive to \( h_R \) and and one exclusively sensitive to \( h_L \). Write the scalar detector response of each of these detectors as

\[
m_{R,L}(t) = \exp[\mu_{R,L}(t) + i\psi_{R,L}(t)],
\]

for real \( \mu_{R,L} \) and \( \psi_{R,L} \). Next, note that the parameters that describe a coalescing binary system can be divided into two groups: those that principally affect only the signal amplitude (i.e., \( \mu(t) \)) and those that affect only or principally the real part of the signal phase (i.e., \( \psi(t) \)). The first group includes distance, source orientation with respect to the observer line-of-sight, and \( \xi \). The second group includes the orbital phase, sky location (through its affect on the Doppler correction to the signal phase as the detector orbits about the sun), the instantaneous binary period at some fiducial moment, and the parameters associated with spin and orbital angular momentum [50]. If we approximate each detector’s noise as white with one-sided noise power spectral density \( S_0 \) then the elements of the inverse covariance matrix \( \Gamma \)—the so-called Fisher matrix—are given by [51,52]

\[
\Gamma_{ij} = \sum_{k=L,R}^2 \frac{2}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{\partial m_k}{\partial x^i} \right] \left[ \frac{\partial m_k}{\partial x^j} \right] dt,
\]

where the integration is over the observation period \((t_i, t_f)\) and the \( x^i \) are the parameters that characterize the incident gravitational wave, which we have divided into two groups. Matrix elements \( \Gamma_{ij} \) where \( x_i \) and \( x_j \) belong to different groups will be much smaller than elements where \( x_i \) and \( x_j \) belong to the same group. Setting the cross-group elements to zero we obtain an approximate \( \Gamma \) that is block diagonal, with one block corresponding to \( \Gamma_{ij} \) with \( (x_i, x_j) \) drawn from the first group, and the other block corresponding to \( \Gamma_{ij} \) with \( (x_i, x_j) \) drawn from the second group. Estimation uncertainties of parameters in either group can now be determined independently of the parameters in the other group.

Focus attention now on those parameters that affect only \( \mu(t) \), the signal’s amplitude evolution. The leading order dependence of the amplitude \( |h_{R,L}| \) on the binary systems parameters is given by

\[
A_{R,L} = |h_{R,L}| = (1 + \lambda_{R,L} \hat{x}_0)^2 \frac{2M}{d_L} \left[ \frac{k_0(t)M}{2} \right]^{2/3} \exp \left( \frac{\lambda_{R,L} \xi - k_0(t)}{H_0} \right),
\]

where \( \mathcal{M} \) is assumed known. Setting aside the antenna pattern factors associated with the projection of the signal onto the LISA detector (which depend only on the known source sky position and the LISA orbital ephemeris), assuming that there is no real precession in the binary system under observation (i.e., \( \hat{x}_0 \)), and that \( k(t) \) is given by Eq. (3.11) the inverse of the covariance matrix—the so-called Fisher matrix, \( \Gamma \)—associated with the amplitude measurements is a symmetric 3 \( \times \) 3 matrix with elements

\[
\Gamma_{DD} = \frac{1}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{2}{1 - \hat{x}_0^2} A_L^2 - \frac{2}{1 + \hat{x}_0^2} A_R^2 \right] dt \approx 8(1 + 6 \hat{x}_0^2 + \hat{x}_0^4) \left( \frac{\mathcal{M}}{d_L} \right)^2 I + O(\xi),
\]

\[
\Gamma_{D\hat{x}_0} = \frac{1}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{2}{1 - \hat{x}_0^2} A_L^2 - \frac{2}{1 + \hat{x}_0^2} A_R^2 \right] dt \approx -16 \hat{x}_0(3 + \hat{x}_0^2) \left( \frac{\mathcal{M}}{d_L} \right)^2 I + O(\xi),
\]

\[
\Gamma_{D\xi} = \frac{1}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{4A_R^2}{(1 + \hat{x}_0^2)} + \frac{4A_L^2}{(1 - \hat{x}_0^2)} \right] dt \approx -64 \hat{x}_0(1 + \hat{x}_0^2) \left( \frac{\mathcal{M}}{d_L} \right)^2 J + O(\xi),
\]

\[
\Gamma_{\hat{x}_0\hat{x}_0} = \frac{1}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{2k_0(t)}{H_0} \right] \left[ \frac{A_R^2}{1 + \hat{x}_0^2} + \frac{A_L^2}{1 - \hat{x}_0^2} \right] dt \approx 32(1 + 3 \hat{x}_0^2) \left( \frac{\mathcal{M}}{d_L} \right)^2 I + O(\xi),
\]

\[
\Gamma_{\hat{x}_0\xi} = \frac{1}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{2k_0(t)}{H_0} \right] \left[ \frac{A_R^2}{1 + \hat{x}_0^2} + \frac{A_L^2}{1 - \hat{x}_0^2} \right] dt \approx 32(1 + 3 \hat{x}_0^2) \left( \frac{\mathcal{M}}{d_L} \right)^2 J + O(\xi),
\]

\[
\Gamma_{\xi\xi} = \frac{1}{S_0} \int_{t_i}^{t_f} \frac{d}{dt} \left[ \frac{2k_0(t)}{H_0} \right] \left[ \frac{A_R^2}{1 + \hat{x}_0^2} + \frac{A_L^2}{1 - \hat{x}_0^2} \right] dt \approx 32(1 + 6 \hat{x}_0^2 + \hat{x}_0^4) \left( \frac{\mathcal{M}}{d_L} \right)^2 K + O(\xi),
\]
where

\[ I = \int_{t_i}^{t_f} \frac{k_0(t)M}{2} \frac{4/3}{S_0} dt = \frac{5}{192} \int_{k_{\text{min}}}^{k_{\text{max}}} \left( kM \right)^{-7/3} \frac{M^2 dk}{S_0} \]

\[ J = \int_{t_i}^{t_f} \frac{k_0(t)M}{2} \frac{7/3}{S_0} dt = \frac{5}{192} \int_{k_{\text{min}}}^{k_{\text{max}}} \left( kM \right)^{-4/3} \frac{M^2 dk}{S_0} \]

\[ K = \int_{t_i}^{t_f} \frac{k_0(t)M}{2} \frac{10/3}{S_0} dt = \frac{5}{192} \int_{k_{\text{min}}}^{k_{\text{max}}} \left( kM \right)^{-1/3} \frac{M^2 dk}{S_0} \]

\[ \mathcal{J} = \int_{t_i}^{t_f} \left( \frac{k_0(t)M}{2} \right)^{10/3} dt \]

\[ \mathcal{K} = \int_{t_i}^{t_f} \left( \frac{k_0(t)M}{2} \right)^{7/3} dt \]

\[ \mathcal{J} = \int_{t_i}^{t_f} \left( \frac{k_0(t)M}{2} \right)^{10/3} dt \]

\[ \mathcal{K} = \int_{t_i}^{t_f} \left( \frac{k_0(t)M}{2} \right)^{7/3} dt \]

and we have taken advantage of the fact that for inspiraling compact binary systems in the quadrupole approximation \( k(t) \) is monotonic in \( t \) to reexpress the integrals over the interval \((t_i, t_f)\) as integrals over \([k(t_i), k(t_f)] = [k_{\text{min}}, k_{\text{max}}]\).

In the particular case of a binary seen plane-on \((\phi_0 = 0)\), the \((\mathcal{D} \phi_0)\) and \((\mathcal{D} \phi)\) blocks of \( \Gamma \) are diagonal, leading to

\[ \nu_{\phi_0, \phi_0} = \frac{1}{4\rho^2} \frac{\mathcal{K} I}{\mathcal{J} - \mathcal{J}^2}, \]

\[ \nu_{\phi, \phi} = \frac{(M \Phi_0)^2}{4\rho^2} \frac{I^2}{\mathcal{K} - \mathcal{J}^2}, \]

where \( \nu_{ij} \) is the ensemble average covariance

\[ \nu_{ij} = \langle \hat{X}_i \hat{X}_j \rangle = \langle \Gamma^{-1} \rangle_{ij}, \]

and we have expressed the \( \nu_{ij} \) in terms of the ensemble average amplitude-squared signal-to-noise ratio \( \rho^2 \)

\[ \rho^2 = \frac{1}{S_0} \int_{t_0}^{t_f} dt (A_k^2 + A_T^2). \]

Focus attention on a binary system of two black holes at redshift \( z \), each with mass \( M = 10^3 M_0 \times (1 + z)^{-1} \). Over the final year before coalescence the radiation wavelength \( 2\pi/k \) observed at the detector will range from \( c(10^{-4} \text{ Hz})^{-1} \) to \( c(10^{-2} \text{ Hz})^{-1} \). For such a system,

\[ \rho = \frac{10^5 \hbar_{100}}{1 + z - \sqrt{1 + z}} \left( \frac{10^{-40} \text{ Hz}^{-1}}{S_0} \right)^{1/2}, \]

\[ \nu_{\phi, \phi} = 3.1 \times 10^{-40} \left( \frac{S_0}{10^{-40} \text{ Hz}^{-1}} \right) (1 + z - \sqrt{1 + z})^2. \]

Observation of binary systems like these at \( z = 15 \) by LISA will be capable of placing a “1-sigma” upper bound on \( \xi \) of order \( 10^{-19} \).

C. How large might \( \xi \) be?

To estimate \( \xi \) (cf. Eq. (3.8c)) we must invoke a theoretical model for the functional \( \theta(\phi(z)) \). As described in the introduction, perturbative string theory requires a Chern-Simons correction to the Einstein-Hilbert action [53]. Here we describe a different mechanism, that can also lead to the presence of a Chern-Simons correction. Consider the backreaction of a \( \mathcal{N} = 1 \) supersymmetric Yang-Mills theory in a curved background (cf. [54] Appendix A) with action

\[ S_{\mathcal{CS}} = \frac{1}{16\pi} \int d^4x \mathcal{J} F(1(S)(R^*R)), \]

where \( S \) is the glueball superfield and \( \mathcal{J} F(1(S)) \), which plays the role of \( \theta \) in Eq. (2.1), can be exactly evaluated by using perturbative matrix model technology developed in [55]. Within this Yang-Mills framework, \( \theta \) is a functional \( \theta(\varphi) \) of some pseudoscalar field \( \varphi \), the gravitational axion, that depends only on conformal time [22]. The functional \( \theta(\varphi) \) can be expressed as

\[ \theta(\varphi) = \mathcal{N} \frac{\ell_{\Pi}^2}{2\pi} \frac{\varphi}{M_\Pi}, \]

leading to

\[ \theta(\varphi) = \frac{\mathcal{N}}{16\pi^2} \frac{\varphi}{M_\Pi} \]

Assuming that \( \varphi \), which has units of inverse length, evolves with the Hubble parameter \( H \propto \eta^{-3} \) we have

\[ A(z) = B(z) = -\Delta T(z)^{(1 + z)^{1/2} - 1}, \]

and

\[ \xi = -\frac{1}{T(z)} \{(1 + z)^{1/2} - 1\} (\epsilon - 2\gamma \zeta), \]

with \( \epsilon \) the order of

\[ \epsilon - 2\gamma \zeta \approx \frac{(1.8 + 3.5h_{100}^2) \times 10^{-120}}{M_\mathcal{F}^2} \left( \frac{\varphi_0}{M_s} \right) \left( \frac{10^{16} \text{ GeV}}{M_s} \right). \]

The size of \( \xi \) thus depends on the present value of the field \( \varphi_0 \), the fundamental string energy scale \( M_s \) and the string coupling \( g_s \), none of which are constrained by present-day theory.

The lesson to draw from the discussion of this scenario is that the magnitude of any Chern-Simons correction de-
pend strongly on the external theoretical framework that prescribes the functional $\theta[\varphi]$. For nonvanishing string coupling in the perturbative string theory scenario the Chern-Simons correction seems undetectable owing to the Planck scale suppression of the decay constant of the universal gravitational axion field $\varphi$. However, this model and the associated expected scale of $e^{-2\gamma\xi}$ applies only to the perturbative sector of string theory and, in particular, when Ramond-Ramond charges are turned off. If present these additional degrees of freedom do couple and source the Chern-Simons correction, leading to a larger decay constant (e.g., D3 branes always excite the Chern-Simons interaction in four dimensions). In a recent work, Svrcek and Witten [56] noted that, due to nonperturbative gravitational instanton corrections, the Chern-Simons coupling in the nonperturbative sector is currently incalculable. Even within the perturbative framework there are theoretical frameworks where $\xi$ could become significant: e.g., if the string coupling $g_s$ vanishes at late times [57–67]. Therefore, within the full string theory framework, a larger coupling, which would push the stringy Chern-Simons correction into the observational window, is not excluded and bounding it places a constraint on string theory motivated corrections to classical general relativity.

As discussed briefly in the introduction, other (non-string) theoretical frameworks lead to a Chern-Simons correction to the Einstein-Hilbert action. In quantum theories Chern-Simons corrections to the Einstein-Hilbert action are required in both the standard model[8] and in loop quantum gravity (where it is required to ensure invariance under large gauge transformations [12]). A Chern-Simons correction can also be introduced $ad hoc$ into the classical theory [16], where it is related to torsion [13,14]. In any of these scenarios—quantum or classical—there is no theoretical constraint on the Chern-Simons coupling to the Einstein-Hilbert action: i.e., a coupling of order unity is theoretically consistent. Moreover, in the presence of fermions the Chern-Simons correction is actually enhanced through axial fermion currents [14]. By bounding this coupling, gravitational-wave observations that can discern the unique birefringence of spacetime associated Chern-Simons gravity thus probe quantum corrections to classical gravity.

V. CONCLUSIONS

Chern-Simons corrections to the Einstein-Hilbert action are strongly motivated by string theory, quantum gravita-tional corrections to the standard model and loop quantum gravity. In all cases these corrections lead to an amplitude birefringence for gravitational waves propagating through space time. We have evaluated the correction to the gravitational waves amplitude that propagate over cosmological distances in a matter-dominated Friedmann-Robertson-Walker cosmology. In the case of the gravitational waves from inspiraling binary black hole systems the effect of the spacetime birefringence is an apparent time-dependent change in the inclination angle between the binary system’s orbital angular momentum and the line-of-sight to the detector. (This change is “apparent” in the same sense that light is apparently “bent” upon passage nearby a strongly gravitating object.) Sufficiently long observations of a binary system will enable this apparent rotation to be distinguished from the real rotation caused by spin-orbit and spin-spin angular momentum interactions in the binary system. Observations of this kind will be possible using the LISA gravitational-wave detector [2–4], which will be able to observe the inspiral of massive black hole binaries at redshifts approaching 30 for periods of a year or more. Gravitational-wave observations of these systems with LISA may thus provide the first test of string theory or other quantum theories of gravity: yet another way in which gravitational-wave observations can act as a unique tool for probing the fundamental nature of the universe.

ACKNOWLEDGMENTS

We are grateful to S. James Gates Jr. for encouraging us to look into the possibility of testing string theories with the Green-Schwarz term. We also thank Lubos Motl, Benjamin Owen, Michael Peskin, Andy Strominger, Emanuele Berti, Clifford Will, Carlos Sopuerta, Eric Poisson, and Scott Hughes for enlightening discussions and comments. In string theory the absence of a Chern-Simons term leads to the Green-Schwarz anomaly. Quantum consistency requires cancellation of this anomaly. In order to eliminate the anomaly, the introduction of a Chern-Simons term is essential. Heterotic M-theory makes use of an anomaly inflow, which also leads to the same requirement.
